

EVALUATION OF DIFFERENT ANALYTICAL PROCEDURES IN THE TRACE ELEMENT ANALYSIS OF A  
LANDFILL LEACHATE

C.M. BOM

National Institute for Water Supply, Voorburg, the Netherlands

ABSTRACT

In four groundwater samples taken at different depths near a waste disposal site at Noordwijk the trace-elements have been measured with different analytical procedures.

Subsequent recovery experiments are recommended to select the optimum analytical procedure for each type of groundwater sampled near the sites.

---

INTRODUCTION

Within the framework of an investigation of groundwater pollution near waste disposal sites, the quantitative determination of trace-elements at different depths was programmed. The concentrations of most trace-elements of interest could not be measured with methods normally used for groundwaters.

The main sources of interference in the trace-element analysis of groundwaters near sites are the relatively high concentrations of Fe, Na, K, Ca, and Mg (2). While the concentrations of these constituents can vary in the groundwaters sampled at different sites, no generally applicable procedure of analysis is available at this moment.

Guidelines in sampling, pretreatment of samples and analysis leading to acceptable results for groundwater samples taken near the same site can be given however.

EXPERIMENTAL

Sampling and preservation

To avoid precipitation of ironhydroxides, and at the same time occlusion of trace-elements in the precipitate, sampling in a nitrogen-gas atmosphere was necessary.

It was noticed that light induced precipitation, therefore black polyethene sampling material was used.

To prevent adsorption of the trace-elements on the wall of the bottle, samples were acidified with nitric acid to pH 2.

## DIGESTION

The selected digestion techniques varied from so-called "open" techniques with aqua regia (A), hydrochloric acid (B), to a "closed" technique (C).

- (A) - After addition of 10 ml aqua regia to 250 ml of the sample, the sample was boiled until the volume was reduced to approximately 200 ml. The sample was cooled and made up to 250 ml with distilled water.
- (B) - An amount of 25 ml hydrochloric acid (conc.) was added to 250 ml of the sample, and treated further in accordance with A.
- (C) - Into an acid digestion bomb (Parr 4745) an amount of 2.0 ml sample and 0.3 ml of nitric acid (conc.) was transferred. After closing the bomb the destruction was carried out at 140 °C during 4 hours. After cooling the content was transferred into a 50 ml measuring flask and made up to volume with distilled water.

Iron removal and preconcentration by complexing with APDC<sup>\*</sup>) and DADDTC<sup>\*</sup>).

A part of the digest (A) was treated with amyacetate to remove iron. Subsequently the trace-elements were preconcentrated with the chelating agents: APDC and DADDTC before measurement with the AAS-flame technique.

- APDC : Ammonium Pyrrolidine-dithiocarbamate
- DADDTC : Diethylammonium-diethyl dithiocarbamate

## ANALYSIS

The digests A, B and C have been measured with atomic absorption spectrometry (AAS) using flame-(I), hydride generating-(II) and graphite furnace techniques (III)

The operating conditions are mentioned in tables 1 and 2.

The reduction reagent, forming the AsH<sub>3</sub> (hydride) was supplied as 2,5 ml of a solution containing 10% NaBH<sub>4</sub> and 2,5% NaOH.

The formed hydride was purged with argon into the quartz measuring cell (cuvet) which was heated at 1000 °C (program 1). The arsenic, from the dissociated AsH<sub>3</sub> was measured with the operating conditions mentioned in Table 1.

The elements: Pb, Cu, Cd were also measured with Differential Pulse Anodic Stripping Voltammetry, to compare the results with the AAS data.

## RESULTS AND DISCUSSION

The same analytical procedures have been performed after addition of a known amount of the element of interest to the sample. The recovery of the concentrations found have been expressed as the percentage of the quantity added (Table 3). The results indicate that with certain combinations of digestion and analytical procedures

acceptable quantities of the additions have been recovered (90-105%).

The low concentrations and recoveries measured after removal of iron and complexation with APDC and DADDTc suggest that this method (I\*) is not applicable to groundwaters with relatively low concentrations of trace-elements. On landfill leachates from Delden and Tilburg, with concentration of trace-elements that are 10-30 times higher than in the groundwater studied, the method was successfully applied however (3).

#### CONCLUSION

For the main part of the trace-elements different concentrations have been found depending upon the analytical procedure applied. Regarding the results of other laboratories it seems that methods leading to acceptable results cannot always be used for the analysis of groundwater samples taken from other sites. With respect to quantitative trace-element analysis it is recommended therefore that groundwater samples taken from the same site should be checked with different analytical procedures. At least the digestion-procedures A, B, C and the analytical technique I(\*), II and III, described in this paper, should be tested. Subsequent recovery experiments should be performed in order to select the optimum analytical procedure.
